

Optimisation of a carbon fibre manhole cover on which an aeroplane should be able to land

force F from the nosewheel of a plane exerted on the manhole

F

Shear stress distribution over the thickness of the manhole due to bending forces

about 60 layers of 250 grams carbon fibre necessary?

the length of the arrow is an indication of the height of the shear stress

Support around the edge of the manhole is made of concrete

When the nose wheel of an aeroplane touches the manhole, bending stresses occur in the manhole. Due to these bending stresses shear stresses will arise through the thickness of the manhole. The shear stresses change in thickness direction. So shear stresses are carried by the resin because there are no fibres in thickness direction. Some fibres are good to handle shear stresses. The resin is very weak in this point of view. In this design the resin must carry shear stresses although resin is not good in it. To overcome this problem a redesign is needed. Just by using a bar made of unidirectional fibres, shear forces can be carried by the fibers. underneath you see this new design. No shear forces have to be carried by the resin anymore. Due to extra strength the expensive carbon fibres can be changed to the much cheaper glass fibres. Both strength, reliability and durability have been improved and production costs are lowered by at least 20%.

Cross sectional drawing of the fibre layers placed in a vacuum mold

Already impregnated and cured unidirectional round glass fibre pieces (blue) are positioned inside holes of circular cut glass fibre. A steel cover is placed and vacuum injection can take place. After curing the glass fibre pieces and the layers of glass fibre become one strong part.

1 of 60 layers glass fibre to be placed in the mold

Vacuum injection mold drawn without a cover

Topview of the vacuum mold

Unidirectional glass fibre means the fibre is orientated only in thickness direction of the manhole

Glass fibre cut round in the right diameter with 9 stamped holes in it. The 9 holes are needed to place the already cured glass fibre in. 5 holes can also be enough to change from carbon to ordinary glass fibre

Just by using some inserts (unidirectional already cured glass fibre) the resin does not need to carry shear stresses. the resin is only good in letting forces go into the fibre. Just by adding some cheap inserts (for sale as standard product so very cheap), the 60 layers of expensive carbon fibre can be replaced with cheap glass fibre. the only extra thing to be done is stamping holes in the layers of glass fibre
